Supporting Information

**ABSTRACT:** The commercial viability of emerging lithium–sulfur batteries (LSBs) remains greatly hindered by short lifespans caused by electrically insulating sulfur, lithium polysulfides ( $\text{Li}_2\text{S}_n$ ;  $1 \leq n \leq 8$ ) shuttling, and sluggish sulfur reduction reactions (SRRs). This work proposes the utilization of a hybrid composed of sulphilic  $\text{MoS}_2$  and mayenite electride ( $\text{C12A7:e}^-$ ) as a cathode host to address these challenges. Specifically, abundant cement-based  $\text{C12A7:e}^-$  is the most stable inorganic electride, possessing the ultimate electrical conductivity and low work function. Through density functional theory simulations, the key aspects of the  $\text{MoS}_2/\text{C12A7:e}^-$  hybrid including electronic properties, interfacial binding with  $\text{Li}_2\text{S}_n$ ,  $\text{Li}^+$  diffusion, and SRR have been unraveled. Our findings reveal the rational rules for  $\text{MoS}_2$  as an efficient cathode host by enhancing its mutual electrical conductivity and surface polarity *via*  $\text{MoS}_2/\text{C12A7:e}^-$ . The improved electrical conductivity of  $\text{MoS}_2$  is attributed to the electron donation from  $\text{C12A7:e}^-$  to  $\text{MoS}_2$ , yielding a semiconductor-to-metal transition. The resultant band positions of  $\text{MoS}_2/\text{C12A7:e}^-$  are well matched with those of conventional current-collecting materials (*i.e.*, Cu and Ni), electrochemically enhancing the electronic transport. The accepted charge also intensifies  $\text{MoS}_2$  surface polarity for attracting polar  $\text{Li}_2\text{S}_n$  by forming stronger bonds with  $\text{Li}_2\text{S}_n$  via ionic Li–S bonds than electrolytes with  $\text{Li}_2\text{S}_n$ , thereby preventing polysulfide shuttling. Importantly,  $\text{MoS}_2/\text{C12A7:e}^-$  not only promotes rapid reaction kinetics by reducing ionic diffusion barriers but also lowers the Gibbs free energies of the SRR for effective  $\text{S}_8$ -to- $\text{Li}_2\text{S}$  conversion. Beyond the reported applications of  $\text{C12A7:e}^-$ , this work highlights its functionality as an electrode material to boost the efficiency of LSBs.

**KEYWORDS:** Li–S batteries, polysulfide shuttling, C12A7 electride, density functional theory, sulfur reduction reaction

## INTRODUCTION

Lithium-ion batteries (LIBs) are currently the mainstream storage devices for portable electronic gadgets and electric vehicles (EVs).<sup>1</sup> Nevertheless, the limited theoretical capacity ( $<387 \text{ Wh kg}^{-1}$ ) of LIBs elusively suffices overwhelming demands for ultrahigh energy densities toward extended-range EVs, smart grid applications, and ambitious electric aviation.<sup>2,3</sup> In this regard, rechargeable lithium–sulfur batteries (LSBs) have emerged as promising alternatives because of their ultimate theoretical energy density of  $2600 \text{ Wh kg}^{-1}$ , around five times greater than LIBs.<sup>4</sup> Moreover, the use of sulfur (*i.e.*, the 10th most earth-abundant element) as an electrode material not only

enhances sustainability due to its abundance but also leverages its status as a byproduct of the petroleum industry.<sup>1</sup> These technical advantages position LSBs as leading contenders among next-generation battery technologies.<sup>5</sup>

Despite their numerous benefits, the technological readiness level of LSBs is around 7–8, meaning full commercialization is not available at the moment.<sup>6</sup> LSBs typically face manifold challenges associated with the intrinsic properties of the cathode, electrolyte, and anode.<sup>5,7</sup> The sulfur cathode is both electronic ( $\sigma_e = 5 \times 10^{-15} \text{ S m}^{-1}$ ) and ionic insulator, which retards electrochemical kinetics.<sup>8</sup> The conversion of elemental sulfur ( $\text{S}_8$ ) into end-product lithium sulfide ( $\text{Li}_2\text{S}$ ) during the sulfur reduction reaction (SRR) involves the subtle 16-electron process (*i.e.*,  $\text{S}_8 + 16\text{Li}^+ + 16\text{e}^- = 8\text{Li}_2\text{S}$ ), yielding various heteropolar lithium polysulfides ( $\text{Li}_2\text{S}_n$ ;  $1 \leq n \leq 8$ ).<sup>9</sup> In particular, the transitions among  $\text{Li}_2\text{S}_n$  are energetically hindered by the sluggish SRR derived from the solid–liquid–solid phase evolution. Additionally, certain high-order polysulfides ( $\text{Li}_2\text{S}_n$ ;  $4 \leq n \leq 8$ ) can be readily dissolved in polar liquid electrolytes, such as common 1,2-dimethoxyethane (DME) and 1,3-dioxolane (DOL).<sup>10</sup> This intricate solubility phenomenon, known as polysulfide shuttling, gradually depletes the active polysulfides, which are subsequently migrated backward to deposit as dendrites at the anode. Consequently, an electrically insulating solid–electrolyte interface is formed at the anode.<sup>10</sup> Thus, the battery's capacity retention and Coulombic efficiency are severely suppressed.<sup>11</sup> Furthermore, the end-product  $\text{Li}_2\text{S}$  of SRR induces substantial volumetric expansion of around 80.0% because of the pronounced difference in volumetric densities between  $\text{S}_8$  and  $\text{Li}_2\text{S}$ .<sup>5</sup> This results in cathode mechanical instability and shortened battery lifespan.<sup>5</sup> Addressing these challenges is essential for enhancing the performance of LSBs.

One feasible route to overcoming these technical challenges is through the strategic utilization of the cathode hosting material, also known as the cathode anchoring material.<sup>12</sup> The host should possess certain desirable features including high electrical conductivity, a sulfiphilic surface, rich surface area, and superior mechanical flexibility.<sup>12</sup> High electrical conductivity is essential for efficient electrochemical reactions.<sup>5</sup> The sulfiphilic characteristics facilitate the anchoring of mobile redox centers to directly use chemically adsorbed polysulfides, which bind to the host stronger than polysulfides with electrolytes (*i.e.*, inhibiting the polysulfide solubility). This accelerates  $\text{Li}_2\text{S}$  chemical kinetics and homogeneous growth.<sup>13</sup> The ultrahigh surface area maximizes polysulfide chemisorption possibilities, thereby improving sulfur utilization.<sup>13</sup> Furthermore, exceptional mechanical flexibility is crucial for tolerating cathode volumetric expansion/contraction during lithiation/delithiation.<sup>5</sup> Given these requirements, generic two-dimensional (2D) materials become the promising candidates due to their high electrical conductivity, planar geometry with enriched surface area and chemistry, and superior mechanical flexibility.<sup>14</sup> Accordingly, numerous works have reported the successful implementations of 2D hosting materials for enhancing the efficiencies of LSBs such as graphene,<sup>15</sup> S-terminated  $\text{Ti}_2\text{C}$  MXenes,<sup>16</sup> biphenylene,<sup>17</sup> carbon nitrides  $\text{C}_x\text{N}_y$ ,<sup>18</sup> germanene,<sup>19</sup> antimonene,<sup>20</sup> and generic transition metal dichalcogenides (TMDs).<sup>21</sup> Their major accomplishments can be attributed to their sulfiphilic nature for effectively inhibiting polysulfide shuttling and their electrocatalytic properties for accelerating electrochemical reactions.

Among various 2D materials, molybdenum disulfide ( $\text{MoS}_2$ ), a reputed 2D material in the family of TMDs, has received intensive attention as the cathode host for LSBs owing to its natural abundance, sulfiphilic nature, ultrafast carrier mobility, less surface dangling bonds with minimal charge trapping, superior mechanical flexibility, and doping engineering and

functionalization of 2D metal chalcogenides.<sup>22</sup> Importantly,  $\text{MoS}_2$  can be mass-produced *via* liquid exfoliation and chemical vapor deposition techniques.<sup>23</sup> Nevertheless, the obtained battery performance of LSBs based on  $\text{MoS}_2$  mandates further improvements (*i.e.*, unfavorable rate performance and poor cycling durability) because of inadequate electrical conductivity and sluggish reaction kinetics during cycling.<sup>24</sup> The electronic conductivity and redox kinetics of  $\text{MoS}_2$  can be exemplarily improved by employing sulfur-doped graphene frameworks supporting atomically dispersed  $2\text{H}-\text{MoS}_2$ ,<sup>25</sup> sodiated  $\text{MoS}_2$ ,<sup>26</sup> and  $\text{MoS}_2/\text{MoN}$  lateral heterostructures.<sup>27</sup> In particular, the enhanced performance in the  $\text{MoS}_2/\text{MoN}$  heterostructure is attributed to the electron donation from MoN to  $\text{MoS}_2$ . As a result,  $\text{MoS}_2$  is n-doped and becomes more electrically conductive to accelerate the redox reaction of polysulfides and smoothen  $\text{Li}^+$  diffusion pathways.<sup>26</sup> Moreover, the concept of heterostructures for magnifying conductivity extends to van der Waals heterostructures (vdWHs)<sup>28</sup> in which distinct 2D materials are vertically assembled *via* vdW interaction. Specifically, vdWHs comprising  $\text{MoTe}_2$  and 2D electride  $[\text{Ca}_2\text{N}]^+:\text{e}^-$  enable ultimate electronic transport of  $\text{MoTe}_2$  (*i.e.*, carrier concentration of  $1.6 \times 10^{14} \text{ cm}^{-2}$  and a prolonged electron diffusion length of around 100 nm).<sup>28</sup> Inspired by these previous works, it is postulated that one can enhance battery performance by rationally utilizing a hybrid cathode host made from sulfiphilic  $\text{MoS}_2$ . This host is coupled with a highly electrically conductive, electron-rich, chemically and thermally stable, low work function, and naturally abundant electron-donor material.

Given the requirements mentioned above, novel electride materials are potential candidates. The electride phase defines peculiar ionic compounds consisting of positively and negatively charged ions.<sup>29</sup> The negative ions are simply electrons without nuclei which are weakly bound in the host structure, thereby acting as an electron gas to render superlative electron transport and a platform for topological materials.<sup>29</sup> In 2003, the earth-abundant mineral mayenite ( $[\text{Ca}_{12}\text{Al}_{14}\text{O}_{33}]^{4+}:\text{4O}^{2-}$  or simply known as C12A7), a compound in the family of cement-based calcium aluminates, was synthesized as the electride variant by extracting  $\text{O}^{2-}$  ions from the C12A7 structure *via* chemical reduction and replacing them by anionic electrons.<sup>30</sup> The resultant chemical formula is  $[\text{Ca}_{12}\text{Al}_{14}\text{O}_{33}]^{4+}:\text{4e}^-$  abbreviated to  $\text{C12A7}:\text{e}^-$ . Unlike air-susceptible 2D electride  $[\text{Ca}_2\text{N}]^+:\text{e}^-$ ,  $\text{C12A7}:\text{e}^-$  is intriguingly the first inorganic electride thermally and chemically stable at ambient conditions.<sup>31</sup>  $\text{C12A7}:\text{e}^-$  exhibits exceptional electrical mobility and transport (conductivity reaching  $1500 \text{ S cm}^{-1}$  at room temperature), excellent electron concentration ( $2.0 \times 10^{23} \text{ cm}^{-3}$ ), ultralow work function (around 2.4 eV),<sup>31</sup> and exceptional mechanical flexibility.<sup>32</sup> The unique features enable numerous applications including superconductivity (the critical temperature 0.2–0.4 K), electron-field emitters,<sup>33</sup> display devices, catalysis for ambient pressure ammonia production,<sup>34</sup> and transparent conductive oxides.<sup>35</sup> Beyond these,  $\text{C12A7}:\text{e}^-$  is a promising material serving as an appropriate electron donor to intensify the electron transport and catalytic surface reactivity of  $\text{MoS}_2$  when combined as a heterostructure. In other words, the  $\text{MoS}_2/\text{C12A7}:\text{e}^-$  hybrid is hypothesized to be an efficient conductive host for circumventing the insulating nature of sulfur, inhibiting the shuttle effect, and enhancing the electrochemical reactions in LSBs.

Herein, this work aims at using the  $\text{MoS}_2/\text{mayenite}$  electride ( $\text{C12A7}:\text{e}^-$ ) hybrid as the cathode host to resolve limitations of

LSBs. Density functional theory (DFT) was employed to unravel the key aspects including electronic properties, the interfacial binding of  $\text{Li}_2\text{S}_n$  on  $\text{MoS}_2/\text{C12A7:e}^-$ ,  $\text{Li}^+$  diffusion, charge transfer mechanism, and SRR. We discovered that the  $\text{MoS}_2/\text{mayenite}$  electrode hybrid as a cathode host can effectively suppress polysulfide shuttling while enhancing reaction kinetics in LSBs. Apart from the known applications of  $\text{C12A7:e}^-$ , this work sheds light on its unique role as an electrode material in LSBs.

## MODELING AND COMPUTATIONAL DETAILS

$\text{MoS}_2/\text{C12A7:e}^-$  was considered as a hosting material for the sulfur cathode. Modeling of the  $\text{MoS}_2/\text{C12A7:e}^-$  atomic structure was based on the optimized  $4 \times 4 \times 1$  supercell of the single-layer  $\text{MoS}_2$  unit cell ( $a = b = 3.18 \text{ \AA}$ ,  $c = 15.00 \text{ \AA}$ ) placed on top of the cubic unit cell of  $\text{C12A7:e}^-$ , resulting in a 166-atom unit cell. The  $\text{C12A7:e}^-(100)$  plane was considered because it was successfully fabricated in the experiment.<sup>36</sup> An adequate 15.0 Å vacuum gap was incorporated in the vertical direction of the pristine  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$  hybrids to eliminate self-interactions among periodic replicas.

DFT *via* the Vienna Ab initio Simulation Package (VASP)<sup>37,38</sup> was employed to unravel the fundamental aspects of LSBs. The gradient-corrected Perdew–Burke–Ernzerhof (PBE) formalism was adopted to describe the exchange–correlation energy.<sup>39</sup> The projector augmented wave was used to circumvent the rapidly oscillating wave functions of electrons near the ion cores.<sup>40</sup> Here, the Mo ( $4p^6 5s^1 4d^5$ ), S ( $3s^2 3p^4$ ), Ca ( $3s^2 3p^6 4s^2$ ), Al ( $3s^2 3p^1$ ), O ( $2s^2 2p^4$ ), and Li ( $1s^2 2s^1$ ) were treated as the valence states in our calculations. Based on the modeled atomic structures, we employed the converged energy cutoff of 600.0 eV with the Brillouin zone integration of  $3 \times 3 \times 1$  ( $9 \times 9 \times 1$ ) Monkhorst–Pack grids for structural optimization (calculation of electronic density of states).<sup>41</sup> The structural optimization relied on the convergence criterion of Hellmann–Feynman forces acting on each atom (*i.e.*, 20.0 meV/Å). The total energies of the modeled structures were iteratively minimized until the energy difference between the two consecutive cycles of electronic self-consistency was less than  $10^{-6}$  eV. Spin–orbit coupling was not considered in our work.

Interfacial interactions of  $\text{Li}_2\text{S}_n$  on  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$  were investigated by evaluating the binding energies ( $E_b$ ) according to the following equation

$$E_b = E[\text{MoS}_2/\text{C12A7:e}^- + \text{Li}_2\text{S}_n] - E[\text{MoS}_2/\text{C12A7:e}^-] - E[\text{Li}_2\text{S}_n] \quad (1)$$

where the first, second, and third terms on the right-hand side of eq 1 define the total energies of  $\text{Li}_2\text{S}_n$ -adsorbed  $\text{MoS}_2/\text{C12A7:e}^-$ , bare  $\text{MoS}_2/\text{C12A7:e}^-$ , and isolated  $\text{Li}_2\text{S}_n$ , respectively. Intrinsic van der Waals (vdW) forces existing at the interface of  $\text{Li}_2\text{S}_n$ – $\text{MoS}_2/\text{C12A7:e}^-$  were considered according to Grimme's DFT-D3 approach.<sup>42</sup> Furthermore, we calculated the ionic diffusion of  $\text{Li}^+$  ions on pristine  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$  using the climbing-image nudged elastic band (CI-NEB) method.<sup>43</sup> Insightful analysis of bonds formed between  $\text{Li}_2\text{S}_n$  and  $\text{MoS}_2/\text{C12A7:e}^-$  was carried out using the crystal orbital Hamilton population (COHP) which applies to studying chemical bonding in absorption, surface processes, and extended solids (*i.e.*, covalent, ionic, and metallic crystals).<sup>44</sup> COHP allocates the band-structure energy (here, DOS outputs from plane-wave-based VASP) to orbital–pair interactions (*i.e.*, bond-weighted DOS of a pair of nearby atoms). A COHP

diagram indicates bonding and antibonding contributions to the band-structure energy. Moreover, the integrated COHP (ICOHP) represents the contribution of a certain bond to the band energy, hinting at the bond strength. Moreover, Bader charge analysis was conducted to quantify the net atomic charges based on the reconstructed (all-electron) valence density.<sup>45</sup>

Moreover, electrochemical reactions in LSBs were investigated through SRR which is of considerable interest for achieving high-density kinetics energy storage.<sup>46</sup> SRR defines a subtle 16-electron process for reversibly converting sulfur  $\text{S}_8$  to the end-product  $\text{Li}_2\text{S}$ . Mathematically, the overall reaction can be written as  $\text{S}_8 + 16\text{Li}^+ + 16\text{e}^- = 8\text{Li}_2\text{S}$  in which there are a series of intermediates  $\text{Li}_2\text{S}_n$  as follows<sup>9</sup>

where \* represents  $\text{Li}_2\text{S}_n$  which is bound on  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$ . The changes in Gibbs free energy ( $\Delta G$ ) at constant pressure and temperature were calculated to quantify the feasibility of chemical reactions according to the equation  $\Delta G = \Delta E + \Delta E_{\text{ZPE}} - T\Delta S$ . Here,  $\Delta E$ ,  $\Delta E_{\text{ZPE}}$ , and  $T\Delta S$  denote the difference in the binding energies of  $\text{Li}_2\text{S}_n$  adsorbed on the host's surface, zero-point energy (ZPE) associated with molecular vibrations of  $\text{Li}_2\text{S}_n$ , and entropy variation between the  $\text{Li}_2\text{S}_n$ -adsorbed  $\text{MoS}_2$  or  $\text{MoS}_2/\text{C12A7:e}^-$  and isolated  $\text{Li}_2\text{S}_n$ . All of the  $\Delta G$  corresponding to the reaction stages (eqs 2–6) were computed as the following expressions

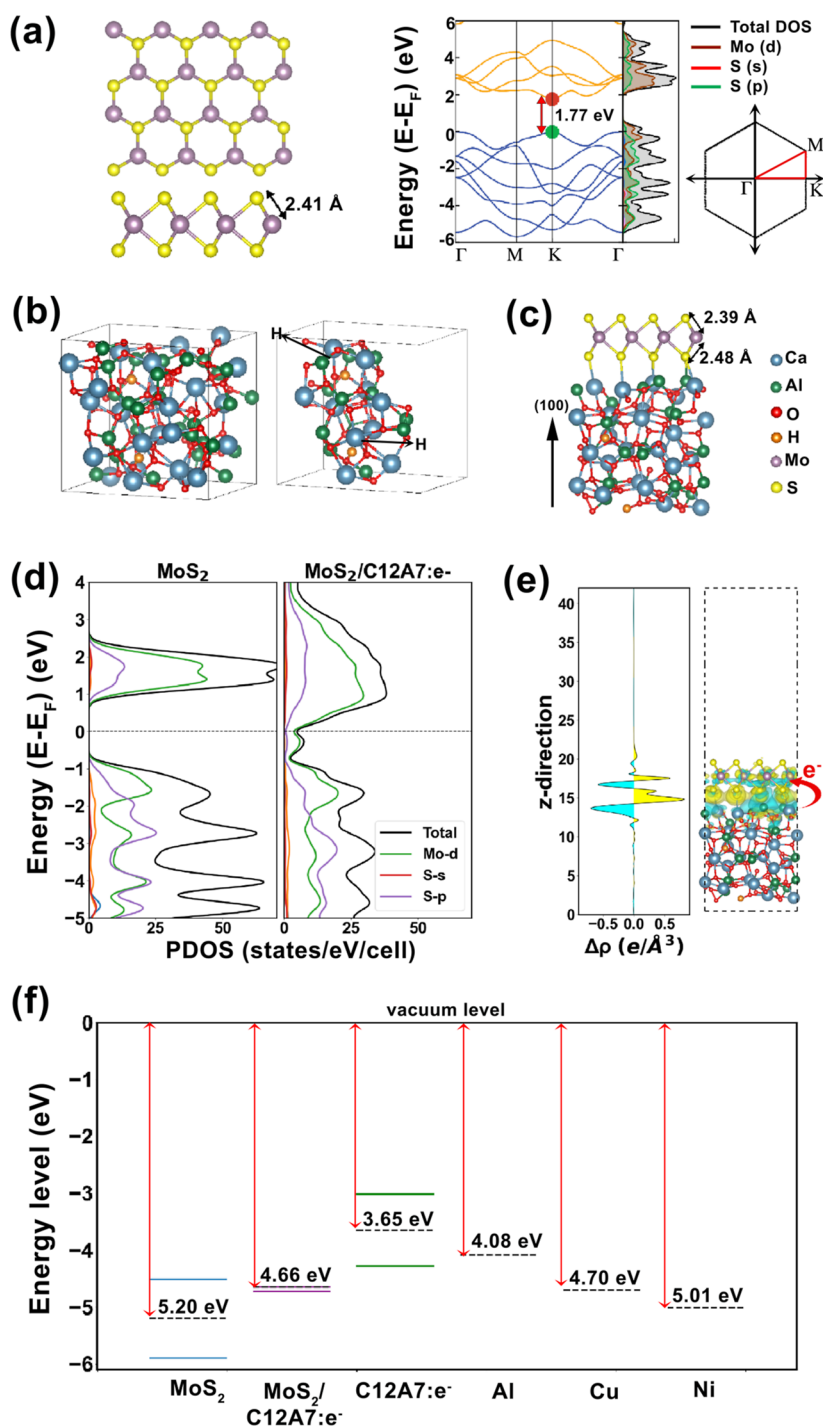

$$\begin{aligned} \Delta G_1 = & [E_{*\text{Li}_2\text{S}_8} + E_{\text{ZPE}(*\text{Li}_2\text{S}_8)} - TS_{*(\text{Li}_2\text{S}_8)}] \\ & + [E_{*\text{S}_8} + E_{\text{ZPE}(*\text{S}_8)} - TS_{*(\text{S}_8)}] \\ & - 2[E_{\text{Li}} + E_{\text{ZPT}(\text{Li})} - TS_{\text{Li}}] \end{aligned} \quad (7)$$

$$\begin{aligned} \Delta G_2 = & [E_{*\text{Li}_2\text{S}_6} + E_{\text{ZPE}(*\text{Li}_2\text{S}_6)} - TS_{*(\text{Li}_2\text{S}_6)}] \\ & + (1/4)[E_{*\text{S}_8} + E_{\text{ZPE}(*\text{S}_8)} - TS_{*(\text{S}_8)}] \\ & - [E_{*\text{Li}_2\text{S}_8} + E_{\text{ZPE}(*\text{Li}_2\text{S}_8)} - TS_{*(\text{Li}_2\text{S}_8)}] \end{aligned} \quad (8)$$

$$\begin{aligned} \Delta G_3 = & [E_{*\text{Li}_2\text{S}_4} + E_{\text{ZPE}(*\text{Li}_2\text{S}_4)} - TS_{*(\text{Li}_2\text{S}_4)}] \\ & + (1/4)[E_{*\text{S}_8} + E_{\text{ZPE}(*\text{S}_8)} - TS_{*(\text{S}_8)}] \\ & - [E_{*\text{Li}_2\text{S}_6} + E_{\text{ZPE}(*\text{Li}_2\text{S}_6)} - TS_{*(\text{Li}_2\text{S}_6)}] \end{aligned} \quad (9)$$

$$\begin{aligned} \Delta G_4 = & [E_{*\text{Li}_2\text{S}_2} + E_{\text{ZPE}(*\text{Li}_2\text{S}_2)} - TS_{*(\text{Li}_2\text{S}_2)}] \\ & + (1/4)[E_{*\text{S}_8} + E_{\text{ZPE}(*\text{S}_8)} - TS_{*(\text{S}_8)}] \\ & - [E_{*\text{Li}_2\text{S}_4} + E_{\text{ZPE}(*\text{Li}_2\text{S}_4)} - TS_{*(\text{Li}_2\text{S}_4)}] \end{aligned} \quad (10)$$

$$\begin{aligned} \Delta G_5 = & [E_{*\text{Li}_2\text{S}} + E_{\text{ZPE}(*\text{Li}_2\text{S})} - TS_{*(\text{Li}_2\text{S})}] \\ & + (1/8)[E_{*\text{S}_8} + E_{\text{ZPE}(*\text{S}_8)} - TS_{*(\text{S}_8)}] \\ & - [E_{*\text{Li}_2\text{S}_2} + E_{\text{ZPE}(*\text{Li}_2\text{S}_2)} - TS_{*(\text{Li}_2\text{S}_2)}] \end{aligned} \quad (11)$$

**Figure 1.** (a) Top and side view of the crystal structure, electronic band structure, and PDOS of MoS<sub>2</sub>. (b,c) Optimized heterostructures of C12A7:e<sup>-</sup> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. (d) PDOS of MoS<sub>2</sub> and optimized heterostructures of MoS<sub>2</sub>/C12A7:e<sup>-</sup>. (e) Charge density difference ( $\Delta\rho$ ) between MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> as calculated by  $\Delta\rho(\vec{r}) = \rho_{\text{MoS}_2/\text{C12A7:e}^-}(\vec{r}) - \rho_{\text{C12A7:e}^-}(\vec{r}) - \rho_{\text{MoS}_2}(\vec{r})$ . The isosurface is set to be 0.001 e/Å<sup>3</sup>. (f) Band alignment diagram of MoS<sub>2</sub>, C12A7:e<sup>-</sup>, MoS<sub>2</sub>/C12A7:e<sup>-</sup> hybrid, and conventional current collectors (e.g., Al, Cu, and Ni).

We set the temperature to ambient 298.15 K. ZPE was obtained by performing vibrational frequency calculations of Li<sub>2</sub>S<sub>n</sub> on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> by calculating the second-order derivatives of the total energy with respect to the ionic positions *via* a method of finite differences. The atomic positions of MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> were fixed during the calculations, whereas those of Li<sub>2</sub>S<sub>n</sub> were allowed to move. Furthermore, the  $\Delta G$  energies for the SRR of Li<sub>2</sub>S<sub>n</sub> in a vacuum

are also comparatively calculated to justify the role of the cathode hosts in the SRR.

## RESULTS AND DISCUSSION

### Structural Properties of MoS<sub>2</sub> and C12A7:e<sup>-</sup> Electride.

As the first step, Figure 1a shows the crystal structure of monolayer MoS<sub>2</sub>. It is classified as a threefold-hexagonal symmetry with the space group P6m2 (no. 187).<sup>47</sup> The S–Mo–S sandwich structure possesses the optimized lattice

constant of  $a = 3.18 \text{ \AA}$ , and the Mo–S and S–S bond lengths are 2.41 and 3.11  $\text{\AA}$ , respectively. These crystallographic parameters are consistent with the reported works.<sup>48</sup> Moreover, the electronic projected density of states (PDOSs) and the corresponding band structure as calculated by the PBE level of theory manifest a finite direct bandgap of 1.77 eV, agreeing with the reported value of 1.80 eV.<sup>49</sup> Meanwhile, Figure 1b shows an optimized unit cell of the C12A7:e<sup>-</sup> electride comprising empty and occupied cages. There are two oppositely charged components including (i) positive  $[\text{Ca}_{24}\text{Al}_{28}\text{O}_{64}]^{4+}$  and (ii) negative  $(\text{H}^-)_2$ . The first part represents a positively charged framework consisting of 12 crystallographic cages. The second part denotes a negatively charged extra-framework that occupies the 2 off-center cages. All cages exhibit  $S_4$  symmetry, where the symmetry axes pass through the cage poles (Ca–Ca). The calculated lattice constant  $a$  is 12.09  $\text{\AA}$ , respectively. The average Ca–Ca distance along the cage poles in empty cages is 5.73  $\text{\AA}$ , whereas that in the cages occupied by electrons is 4.18  $\text{\AA}$ . The electronic density of states and band structure of C12A7:e<sup>-</sup> are shown in Figure S1.<sup>50</sup>

Subsequently, Figure 1c depicts the relaxed atomic geometry of the  $\text{MoS}_2/\text{C12A7:e}^-$  heterostructure.  $\text{MoS}_2$  in the hybrid shows slight deformation as evidenced by the infinitesimal 0.83% deviation in the Mo–S bond lengths (2.39 and 2.48  $\text{\AA}$  as compared with original 2.41  $\text{\AA}$  in pristine  $\text{MoS}_2$ ). Likewise, the crystal structure of C12A7:e<sup>-</sup> in the heterostructure remains virtually retained as compared to the original C12A7:e<sup>-</sup> because there are small expansions in Ca–O and Al–O distances at the interface. Quantitatively, the Ca–O and Al–O distances at the surface before (after) making the heterostructure are 2.28  $\text{\AA}$  (2.34  $\text{\AA}$  and 1.82  $\text{\AA}$  (1.84  $\text{\AA}$ ), amounting to 6.0 and 1.0% enlargements, respectively. Hence, both  $\text{MoS}_2$  and C12A7:e<sup>-</sup> nearly conserved their structural features after being merged into the heterostructure. This implies that the fabricated  $\text{MoS}_2/\text{C12A7:e}^-$  sample exhibits X-ray diffraction patterns of the component materials resembling their bulk counterparts. Intriguingly, there are bridging S–Ca bonds with the average bond distance of 2.48  $\text{\AA}$  formed at the boundary. This length is close to the sum of the ionic radii of Ca (1.84  $\text{\AA}$ ) and S (1.00  $\text{\AA}$ ) atoms<sup>51</sup> and 2.549  $\text{\AA}$  of an ionic Ca–S bond in rock-salt  $\text{CaS}$ ,<sup>52</sup> indicating that the interface is dominated by ionic chemisorption.

Figure 1d comparatively shows the PDOS of  $\text{MoS}_2$  before and after being combined with C12A7:e<sup>-</sup>.  $\text{MoS}_2$  in the  $\text{MoS}_2/\text{C12A7:e}^-$  heterostructure adopts the metallic state characterized by the finite states of S-3p and Mo-4d orbitals at the Fermi energy. The resultant metallic character of  $\text{MoS}_2$  as an electrode material is beneficial for enhancing the electrochemical process in LSBs.<sup>5</sup> Such semiconductor-to-metal transition is attributed to the formation of ionic S–Ca bonds at the boundary because the S atoms are highly more electronegative than the Ca atoms.<sup>53</sup> This results in notable charge transfer from C12A7:e<sup>-</sup> to  $\text{MoS}_2$  as evidenced by the charge density difference plot in Figure 1e. Quantitatively, Bader charge analysis further indicates that Mo and interfacial S atoms accept  $0.12e^-$  from C12A7:e<sup>-</sup>, yielding the modification of Mo–S bond distances. Furthermore, the charge transfer mechanism is also contributed by the electron flow from C12A7:e<sup>-</sup> to  $\text{MoS}_2$  because of the lower work function of the former as depicted in Figure 1f. The accepted charges in  $\text{MoS}_2$  help intensify the surface chemical reactivity for interacting with heteropolar  $\text{Li}_2\text{S}_n$ . The work function of  $\text{MoS}_2/\text{C12A7:e}^-$  is calculated to be 4.65 eV which is well matched with those of current-collecting

materials of battery devices such as Cu (4.70 eV) and Ni (5.01 eV).<sup>54</sup> The metallic feature of  $\text{MoS}_2$  and the appropriate work function of  $\text{MoS}_2/\text{C12A7:e}^-$  consequently facilitate electronic transport for accelerating the electrochemical process in LSBs.

#### Binding characteristics of $\text{Li}_2\text{S}_n$ with $\text{MoS}_2$ and $\text{MoS}_2/\text{C12A7:e}^-$

It is expected that charge donation from C12A7:e<sup>-</sup> to  $\text{MoS}_2$  enhances  $\text{MoS}_2/\text{C12A7:e}^-$  surface affinity toward heteropolar  $\text{Li}_2\text{S}_n$ .<sup>13</sup> Pristine  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$  heterostructure are then utilized as the cathode host material to anchor  $\text{Li}_2\text{S}_n$  binding.<sup>55</sup>  $\text{Li}_2\text{S}_n$ -DME/DOL binding is also considered as a reference for justifying polysulfide shuttling suppression. The lowest-energy conformation of each  $\text{Li}_2\text{S}_n$  adsorbed on  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$  is obtained by attempting various adsorption orientations and sites. Figure 2 exclusively assembles the lowest-energy atomic configurations of  $\text{Li}_2\text{S}_n$  adsorbed on

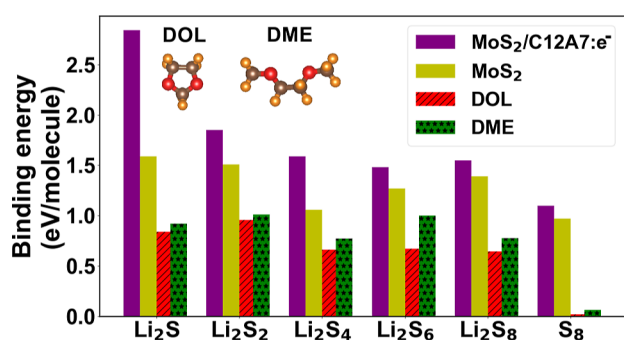

Figure 2. Optimized structures of  $\text{Li}_2\text{S}_n$  adsorbed on (a)  $\text{MoS}_2$  and (b)  $\text{MoS}_2/\text{C12A7:e}^-$ .

MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. One can see that S<sub>8</sub> energetically adopted the parallel orientation on both MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> for intensifying the interfacial interaction, resembling the horizontal adsorption configuration observed in 2D anchoring materials such as graphene,<sup>55</sup> black phosphorene,<sup>56</sup> Fe<sub>3</sub>C,<sup>57</sup> and MXenes.<sup>16</sup> The bond distances from S<sub>8</sub> to MoS<sub>2</sub> (MoS<sub>2</sub>/C12A7:e<sup>-</sup>) are 3.37 (3.27) Å which are twice the atomic radius of S (1.00 Å).<sup>51</sup> Hence, S<sub>8</sub> is physisorbed on MoS<sub>2</sub> (MoS<sub>2</sub>/C12A7:e<sup>-</sup>) via predominant vdW forces. Notably, the relatively shorter S<sub>8</sub>–MoS<sub>2</sub>/C12A7:e<sup>-</sup> distance manifests that S<sub>8</sub> on MoS<sub>2</sub>/C12A7:e<sup>-</sup> experiences enhanced interaction than that in pristine MoS<sub>2</sub>.

Meanwhile, Li<sub>2</sub>S<sub>n</sub> is adsorbed on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> by forming Li–S bonds. This scenario is likely driven by the drastic difference in the electronegativity values between S (2.58) and Li (0.98).<sup>53</sup> The energetically dissociative adsorption of all polysulfides on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> is not observed, ensuring Li<sub>2</sub>S<sub>n</sub> conversion reversibility in the redox reaction. Li<sub>2</sub>S<sub>n</sub>–MoS<sub>2</sub> bond distances range from 2.20 to 2.58 Å. These distances are within the combination of atomic radii of S (1.00 Å) and Li (1.45 Å),<sup>51</sup> characterizing the chemical S–Li bonds formed at the boundary. Notably, the MoS<sub>2</sub>/C12A7:e<sup>-</sup> composite induces a stronger interaction with Li<sub>2</sub>S<sub>n</sub>. The shortened bond distances of Li<sub>2</sub>S<sub>n</sub>–MoS<sub>2</sub>/C12A7:e<sup>-</sup> range from 2.08 to 2.58 Å. In addition, we calculated the binding energies associated with the structural conformations presented by using eq 1. All obtained binding energies are negative, indicating the attractive interaction. However, Figure 3 shows

**Figure 3.** Magnitudes of binding energies of Li<sub>2</sub>S<sub>n</sub> adsorbed on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. Here, DOL and DME abbreviate 1,3-dioxolane and 1,2-dimethoxyethane, respectively, which are common electrolytes used in LSBs.

the strengths of the binding energies ( $E_b$ ) of S<sub>8</sub> and Li<sub>2</sub>S<sub>n</sub> on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. There are significant differences in the adsorption energies of Li<sub>2</sub>S<sub>4</sub>, Li<sub>2</sub>S<sub>2</sub>, and Li<sub>2</sub>S adsorbed on pristine MoS<sub>2</sub> compared to their adsorption on MoS<sub>2</sub>/C12A7:e<sup>-</sup>. This is due to the markedly different geometrical orientations of Li<sub>2</sub>S<sub>4</sub>, Li<sub>2</sub>S<sub>2</sub>, and Li<sub>2</sub>S adsorbed on pristine MoS<sub>2</sub> vs those on MoS<sub>2</sub>/C12A7:e<sup>-</sup>. In contrast, Li<sub>2</sub>S<sub>6</sub>, Li<sub>2</sub>S<sub>8</sub>, and S<sub>8</sub> exhibit virtually similar orientations on both MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>, resulting in less pronounced differences in the adsorption energies. The Li<sub>2</sub>S<sub>n</sub> is adsorbed on MoS<sub>2</sub> with competitively stronger  $E_b$  than DME and DOL, in accordance with reported works.<sup>58</sup> Besides, the MoS<sub>2</sub>/C12A7:e<sup>-</sup> heterostructure further strengthens the interactions with polysulfide species compared with pristine MoS<sub>2</sub>. The  $E_b$  values of Li<sub>2</sub>S<sub>n</sub> on MoS<sub>2</sub>/C12A7:e<sup>-</sup> surpass those on DME and DOL. In particular, MoS<sub>2</sub>/C12A7:e<sup>-</sup> greatly maximizes the binding of the liquid high and medium S-content polysulfides (Li<sub>2</sub>S<sub>n</sub>, where  $n = 8, 6,$

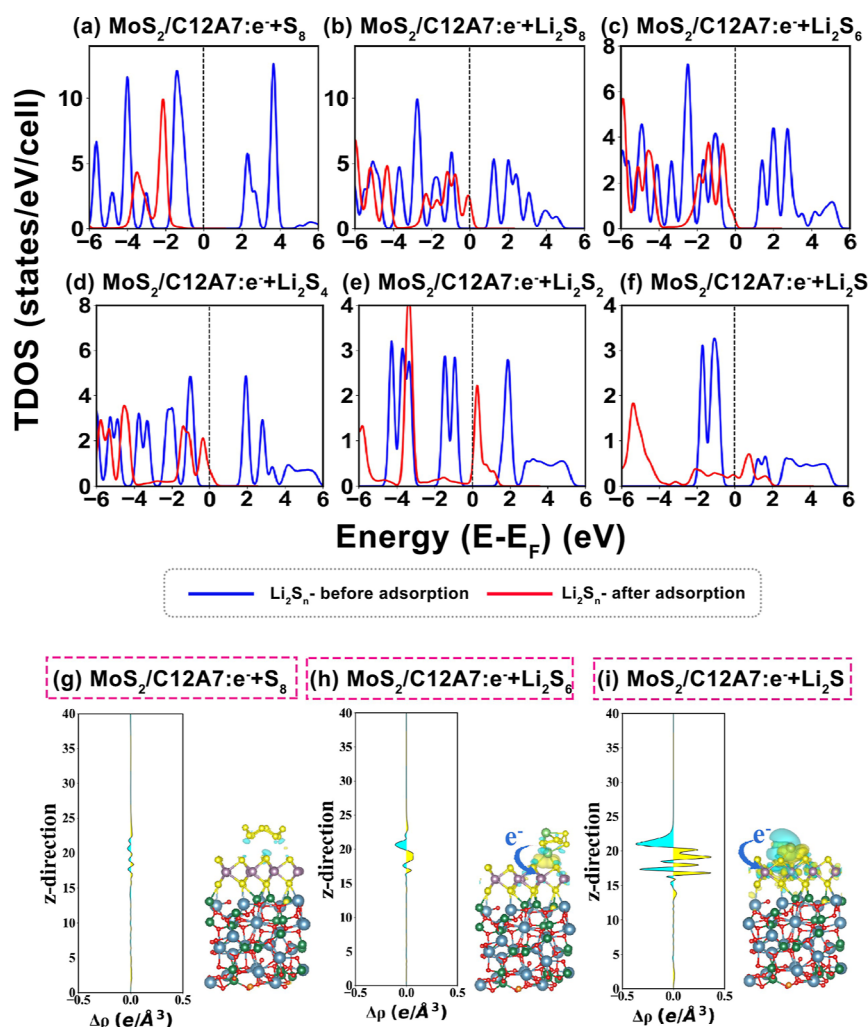

and 4) which are the liquid phases and highly susceptible to dissolution (*i.e.*, the major cause of polysulfide shuttling).<sup>9</sup> Hence, it is conclusive that MoS<sub>2</sub>/C12A7:e<sup>-</sup> as the cathode host effectively suppresses polysulfide shuttling.

**Electronic Properties of MoS<sub>2</sub>/C12A7:e<sup>-</sup> Interacting with Li<sub>2</sub>S<sub>n</sub>.** The strong binding affinities between Li<sub>2</sub>S<sub>n</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are responsible for the suppression of polysulfide shuttling. Moreover, analyzing the variations in the electronic properties of Li<sub>2</sub>S<sub>n</sub> when interacting with MoS<sub>2</sub>/C12A7:e<sup>-</sup> is crucial for comprehending the chemical bonds formed between Li<sub>2</sub>S<sub>n</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. Figure 4a–f displays the total density of states (TDOSs) of Li<sub>2</sub>S<sub>n</sub> before and after adsorption. The bulk sulfur (cyclo-S<sub>8</sub>) is categorized as an insulator because of its large finite energy gap. Notably, the TDOS of S<sub>8</sub> undergoes a notable change after adsorption. Likewise, all Li<sub>2</sub>S<sub>n</sub> intermediates are characterized as electrical insulators owing to the finite energy gaps. Their TDOSs undergo remarkable variations after interacting with MoS<sub>2</sub>/C12A7:e<sup>-</sup>, attesting to chemisorption. Furthermore, we calculated charge density difference ( $\Delta\rho$ ) to support TDOS analysis according to the following expression

$$\Delta\rho = \rho[\text{MoS}_2/\text{C12A7:e}^- + \text{Li}_2\text{S}_n] - \rho[\text{MoS}_2/\text{C12A7:e}^-] - \rho[\text{Li}_2\text{S}_n] \quad (12)$$

where the first, second, and third terms on the right-hand side of eq 12 represent the electron density of the Li<sub>2</sub>S<sub>n</sub>-adsorbed MoS<sub>2</sub>/C12A7:e<sup>-</sup>, MoS<sub>2</sub>/C12A7:e<sup>-</sup>, and the corresponding isolated Li<sub>2</sub>S<sub>n</sub> molecule, respectively. Figure 4c,d illustrates  $\Delta\rho$  of the polysulfides adsorbed on MoS<sub>2</sub>/C12A7:e<sup>-</sup>. The adsorption of bulk S<sub>8</sub> on MoS<sub>2</sub>/C12A7:e<sup>-</sup> causes insignificant charge redistribution, consistent with the weak  $E_b$  values and indicative of predominant physisorption. By contrast, the charge transfer becomes pronounced in the case of Li<sub>2</sub>S<sub>6</sub>, supporting enhanced  $E_b$  values and a tendency toward predominant chemisorption. Specifically, Li<sub>2</sub>S<sub>6</sub> donates charges to the MoS<sub>2</sub>/C12A7:e<sup>-</sup> host, resulting in an upshift in the TDOS of the host, as described previously. Likewise, charge transfer is particularly immense in Li<sub>2</sub>S, supporting the notion of prominent chemisorption.

Additionally, the amount of charge transfer is computed using the Bader charge approach, as shown in Figure 5a. Quantitatively, S<sub>8</sub>, Li<sub>2</sub>S<sub>6</sub>, and Li<sub>2</sub>S donate 0.0004e (0.0005e), 0.003e (0.006e), and 0.02e (0.03e) to MoS<sub>2</sub> (MoS<sub>2</sub>/C12A7:e<sup>-</sup>), respectively. The donated charges consequently magnify the Li<sub>2</sub>S<sub>n</sub>–MoS<sub>2</sub>/C12A7:e<sup>-</sup> interactions as shown by the analysis of PDOS and COHP in Figure 5b–d. The S-3p orbitals from S<sub>8</sub> weakly interact with those from MoS<sub>2</sub>/C12A7:e<sup>-</sup>, resulting in infinitesimal ICOHP of –0.097 eV/bond. By contrast, there are immense chemical interplays among Li-2s of Li<sub>2</sub>S<sub>n</sub> (here, selectively shown by high S-content Li<sub>2</sub>S<sub>6</sub> and low S-content Li<sub>2</sub>S), S-3s, and S-3p orbitals of MoS<sub>2</sub>/C12A7:e<sup>-</sup>, as indicated by the antibonding peaks in the conduction band. These antibonding peaks are derived from the charge donation from the Li-2s state to S-3s and S-3p states to form antibonding states of ionic Li–S bonds above the Fermi energy. Moreover, these bonds possess pronounced bond energies, as indicated by the maximized ICOHP of –0.539 and –0.767 eV/bond for Li<sub>2</sub>S<sub>6</sub> and Li<sub>2</sub>S, respectively. Note that the shape of the Mo-4d states remains nearly conserved during the interaction with Li<sub>2</sub>S<sub>n</sub>. This is because the atomic geometry of MoS<sub>2</sub> comprises the Mo atoms in the central sublayer sandwiched by the outer S atoms. Thus, they do not directly interact with Li<sub>2</sub>S<sub>n</sub>.<sup>59</sup> Based on our

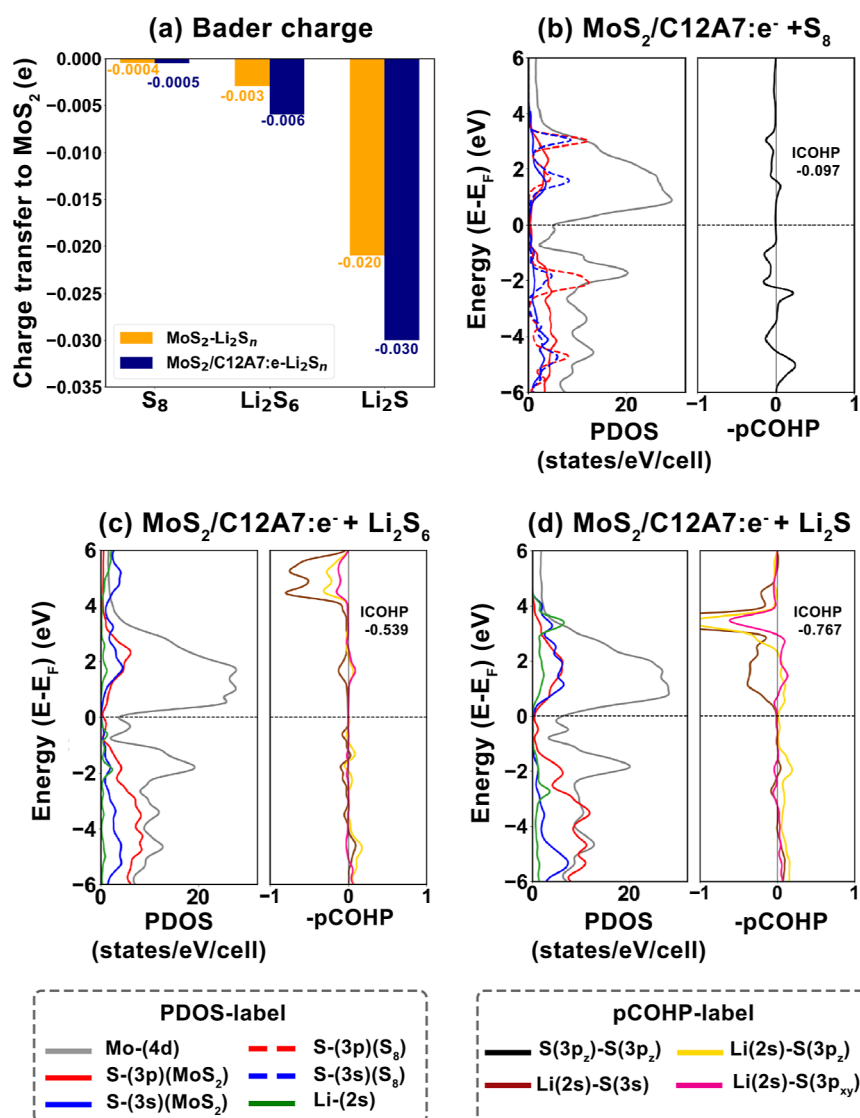

**Figure 4.** (a–f) TDOS of Li<sub>2</sub>S<sub>n</sub> before and after interacting with MoS<sub>2</sub>/C12A7:e<sup>-</sup>. The Fermi energy is shifted to zero for the sake of comparative visualization. (g,i) Charge density difference between Li<sub>2</sub>S<sub>n</sub>-adsorbed MoS<sub>2</sub>/C12A7:e<sup>-</sup>.

analysis of electronic properties, charge-transfer ionic Li–S bonds formed at the Li<sub>2</sub>S<sub>n</sub>–MoS<sub>2</sub>/C12A7:e<sup>-</sup> interface are conclusively responsible for mitigating polysulfide dissolution in DOL and DME electrolytes.

**Li<sup>+</sup> Ionic Diffusion.** Li<sup>+</sup> ionic diffusivity on the cathode of LSBs plays a central role in the reaction kinetics of polysulfide conversion in the redox reaction process as probed by an electrochemical current–voltage measurement.<sup>60</sup> The Li<sup>+</sup> ions energetically favor the low diffusion energy to maximize the diffusion rate basically according to Arrhenius equation  $k = Ae^{-E_a/RT}$ , where  $k$ ,  $A$ ,  $E_a$ ,  $R$ , and  $T$  represent the rate constant, frequency factor depending on the lattice vibrations of diffusion state, diffusion barrier, universal gas constant, and temperature, respectively.<sup>61</sup> In particular, low diffusion energy at a finite temperature on the surface of anchoring materials can particularly enhance the chemical reaction between lithium (anode) and sulfur (cathode).<sup>62</sup> According to this, we compute the diffusion barriers of Li<sup>+</sup> ions on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> using the CI-NEB approach to justify the catalytic anchoring roles of MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> in lowering the diffusion potentials. Figure 6a–c shows the diffusion profiles and most energetic paths of the Li<sup>+</sup> ion on MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. The preferential route is obtained by considering the path connecting two neighboring points on the surfaces of MoS<sub>2</sub> and

MoS<sub>2</sub>/C12A7:e<sup>-</sup> at which the  $E_b$  values of Li<sup>+</sup> are the strongest. The diffusion barriers of Li<sup>+</sup> on pristine MoS<sub>2</sub>, interfacial-strained MoS<sub>2</sub>, and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are 0.25,<sup>63</sup> 0.15, and 0.12 eV, respectively. The interfacial-strained MoS<sub>2</sub> here defines the intrinsic strain imposed by the lattice mismatch between MoS<sub>2</sub> and C12A7:e<sup>-</sup>. The reduction in the ionic diffusion barrier in MoS<sub>2</sub>/C12A7:e<sup>-</sup> is simultaneously contributed by (i) the interfacial strain imposing on MoS<sub>2</sub> from the lattice incompatibility and (ii) the charge transfer between MoS<sub>2</sub> and C12A7:e<sup>-</sup>. Notably, the strain plays a more dominating role, accounting for more than 50% of the barrier reduction. The pathway follows a curved trajectory between the adjacent hollow sites of the Mo–S hexagons.<sup>62</sup> This is because the ion follows the path experiencing less potential, which is the hollow site above the inner Mo atoms. The presence of C12A7:e<sup>-</sup> remarkably reduces the barrier, evidencing its catalytic ability for Li<sup>+</sup> ions' mobility when in contact with MoS<sub>2</sub>. Moreover, the obtained values are among the lowest as compared to those of 2D materials such as graphene (0.32 eV),<sup>64</sup> single-atom-catalyzed graphene,<sup>65</sup> a family of metal sulfides (0.12–0.26 eV),<sup>60</sup> and Ti<sub>2</sub>CS<sub>2</sub> MXenes (0.12 eV),<sup>16</sup> all calculated from the similar DFT-based NEB approach. The variations in the ionic potential profiles of MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are associated with the metallic nature of MoS<sub>2</sub> in the MoS<sub>2</sub>/C12A7:e<sup>-</sup> hybrid as compared with the

**Figure 5.** (a) Bar chart of Bader charge transfer from Li<sub>2</sub>S<sub>n</sub> to MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>. (b–d) PDOS of Li<sub>2</sub>S<sub>n</sub>-adsorbed MoS<sub>2</sub>/C12A7:e<sup>-</sup> in which the corresponding COHP and ICOHP of the bonds between Li (S) of Li<sub>2</sub>S<sub>n</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are also shown.

original semiconducting MoS<sub>2</sub>. According to the d-band model in metal catalysts,<sup>66</sup> the d-band center ( $\epsilon_d$ ) is quantitatively computed by the following expression

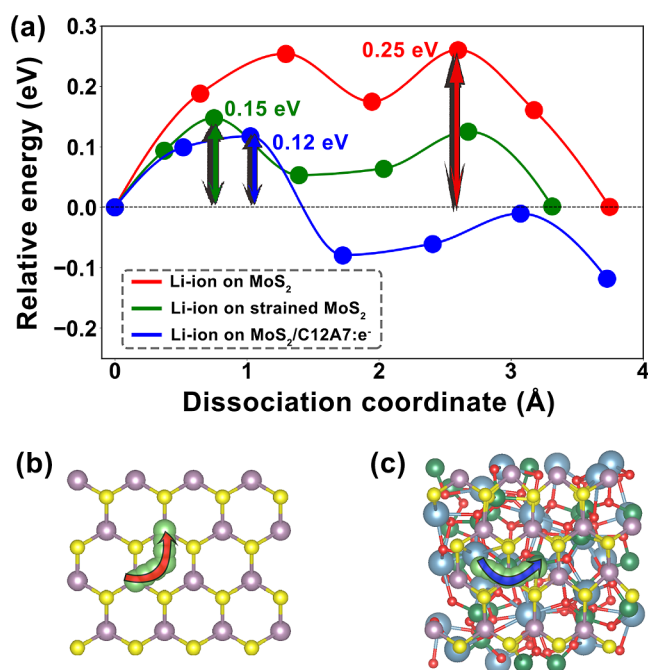

$$\epsilon_d = \frac{\int_{-\infty}^{+\infty} n_d \epsilon d\epsilon}{\int_{-\infty}^{+\infty} n_d d\epsilon} \quad (13)$$

where  $\epsilon$  and  $n_d$  denote the energy and DOS of the Mo-3d states integrated in a particular range of energy. Moreover, the p-band centers are determined using the same concept as in eq 13.<sup>9</sup> The  $\epsilon_d$  values of Mo-3d states in MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are -3.08 and -3.03 eV, respectively. The values of Mo p-band centers in MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are -3.335 and -3.554 eV, respectively. Meanwhile, those of S p-band centers in MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> are -3.463 and -3.722 eV, respectively. In particular, the upshift in the S-3p states intensifies the interaction with Li-s states, being consistent with the COHP bonding analysis and Bader charge analysis as presented in the former section.<sup>9</sup>

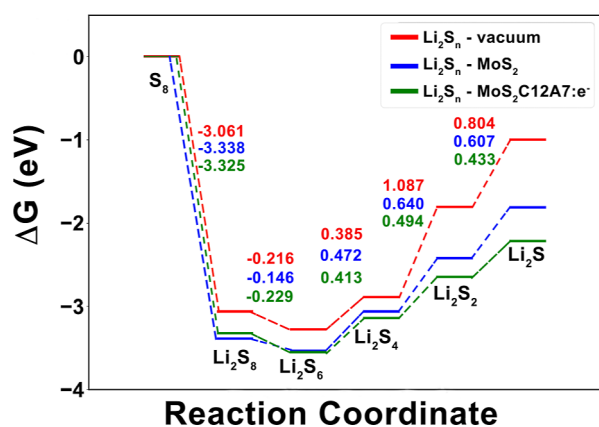

**Sulfur Reduction Reaction.** The sluggish SRR is one of the major intrinsic drawbacks plaguing the efficiencies of the LSBs.

This also results in the extended exposure time of Li<sub>2</sub>S<sub>n</sub> to the electrolytes, worsening the shuttle phenomenon and inefficient sulfur utilization.<sup>5</sup> In addition to the improved ionic diffusivity, we elucidate how MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup> cathode hosts contribute to accelerating the SRR during the operation of the LSBs. Figure 7a shows the  $\Delta G$  profiles of the SRR of transforming S<sub>8</sub> to Li<sub>2</sub>S in the presence of MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>, as calculated from eq 2. The first steps  $\Delta G_1$  for converting solid S<sub>8</sub> to liquid Li<sub>2</sub>S<sub>8</sub> are the spontaneously exothermic processes ( $\Delta G < 0$ ) on both MoS<sub>2</sub> and MoS<sub>2</sub>/C12A7:e<sup>-</sup>, releasing the energies of -3.338 and -3.325 eV, respectively. The initial transition from the S<sub>8</sub> ring to the long-chain Li<sub>2</sub>S<sub>8</sub> is an energetically favorable process as found experimentally.<sup>9</sup> Comparatively, the obtained values are even less than -3.016 eV for converting solid S<sub>8</sub> to liquid Li<sub>2</sub>S<sub>8</sub> in vacuum. This means that the processes with the cathode hosts enable the release of more energy to allow Li<sub>2</sub>S<sub>8</sub> to be in a more stable state than that in the vacuum. This corroborates with the occurrence of Li<sub>2</sub>S<sub>8</sub> in the discharging voltage profile.<sup>5</sup> Likewise, the second reduction steps  $\Delta G_2$  for the Li<sub>2</sub>S<sub>8</sub>-to-Li<sub>2</sub>S<sub>6</sub> transition on MoS<sub>2</sub>, MoS<sub>2</sub>/C12A7:e<sup>-</sup>, and in vacuum remain the

**Figure 6.** (a) Diffusion barriers of  $\text{Li}^+$  ion and (b,c) corresponding path on  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$ .

**Figure 7.** Gibbs free-energy profile of the sulfur reduction in a vacuum, on  $\text{MoS}_2$ , and on  $\text{MoS}_2/\text{C12A7:e}^-$ .

spontaneously exothermic processes with the significantly reduced energies of  $-0.146$ ,  $-0.229$ , and  $-0.216$  eV, respectively. This indicates the catalytic contribution of  $\text{MoS}_2/\text{C12A7:e}^-$  in accelerating the activity toward  $\text{Li}_2\text{S}_6$ .<sup>67</sup> On the other hand, the remaining processes including  $\Delta G_3$  ( $\text{Li}_2\text{S}_6$ -to- $\text{Li}_2\text{S}_4$ ),  $\Delta G_4$  ( $\text{Li}_2\text{S}_4$ -to- $\text{Li}_2\text{S}_2$ ), and  $\Delta G_5$  ( $\text{Li}_2\text{S}_2$ -to- $\text{Li}_2\text{S}$ ) are all endothermic. Among all discharge states, the conversion from  $\text{Li}_2\text{S}_4$  to  $\text{Li}_2\text{S}_2$  notably serves as the rate-determining step requiring  $0.640$ <sup>68</sup> and  $0.494$  eV on  $\text{MoS}_2$  and  $\text{MoS}_2/\text{C12A7:e}^-$ , respectively. This manifests that the  $\text{MoS}_2/\text{C12A7:e}^-$  hybrid plays a superior role in SRR than does  $\text{MoS}_2$  alone. According to eq 10, the obtained rate-limiting step is predominantly ascribed to the increase in the binding energy and entropy from  $\text{Li}_2\text{S}_4$  to  $\text{Li}_2\text{S}_2$ . Additionally, this elusive  $\text{Li}_2\text{S}_4$ -to- $\text{Li}_2\text{S}_2$  transition is typical in the SRR of LSBs and it is confirmed by various independent experimental studies (see the review<sup>5</sup>). For the sake of comparison, this value is among the lowest with other 2D cathode hosts in LSBs, such as  $0.513$  eV of boron nitride<sup>69</sup> and nitrogen-doped graphene  $0.72$  eV.<sup>70</sup> Overall, it is conclusive that

$\text{MoS}_2/\text{C12A7:e}^-$  as the cathode host can enhance the electrical transport of the cathode, suppress the shuttle effect, and offer efficient electrochemical kinetics.

## CONCLUSIONS

In conclusion, we carried out first-principles DFT simulations to investigate the key aspects including electronic properties, interfacial binding,  $\text{Li}^+$  diffusion, charge transfer mechanism, and SRR of LSBs by using  $\text{MoS}_2/\text{C12A7:e}^-$  as a cathode host. The findings indicate that the  $\text{MoS}_2/\text{C12A7:e}^-$  hybrid boosts battery efficiency over  $\text{MoS}_2$ .  $\text{MoS}_2$  in the hybrid undergoes a semiconductor-to-metal transition, induced by electron donation from lower work function  $\text{C12A7:e}^-$ . Moreover, the resultant band positions of  $\text{MoS}_2/\text{C12A7:e}^-$  are well matched with those of the current collecting materials (*i.e.*, Cu and Ni). The hybrid cathode host effectively prevents polysulfide shuttling by forming stronger bonds with  $\text{Li}_2\text{S}_n$  than with electrolytes with  $\text{Li}_2\text{S}_n$ . This is because of charge-transfer ionic  $\text{Li-S}$  bonds. Importantly,  $\text{MoS}_2/\text{C12A7:e}^-$  not only promotes rapid reaction kinetics by reducing energy barriers for the  $\text{Li}^+$  diffusion but also lowers the Gibbs free energies of the SRR for the effective  $\text{S}_8$ -to- $\text{Li}_2\text{S}$  conversion.
